Abstract
A simple and intuitive formulation is reviewed for the Brewster prism-pair - A most common component in spectroscopy-oriented experiments using ultrashort pulses. This review aims to provide students and beginners in the field of spectroscopy with a unified description of a major experimental component. The total spectral phase experienced by a broadband light field is calculated after passing through a pair of Brewster-cut prisms, demonstrating the flexibility of the prism pair to provide tuned, low-loss control of the dispersion and spectral phase experienced by ultrashort pulses.

Introduction
The generation of ultrashort pulses [1,2] revolutionized the field of molecular spectroscopy [3]. Not only that ultrashort pulses enable to observe molecular motion in time [4-6], but they allow also manipulation of the molecular dynamics [7-9] by controlling the spectral properties of the pulses. For this end, many types of pulse-shaping techniques and configurations are common in spectroscopy-oriented experiments. When complete control of the spectral amplitude and phase is required, a general Fourier-domain pulse-shaper [10] can be used, which provides independent control of both phase and amplitude for each frequency component of the light (e.g. with a spatial light modulator [11,12] or deformable mirrors [13]). However, most applications require only much simpler control of the group delay dispersion (GDD) and higher order dispersion to compensate for the dispersive effect experienced by an ultrashort pulse when passing through optical media and setups. For these applications, the high internal loss and technical complexity of a general pulse-shaper are a burden, and simpler configurations are commonly used, such as the grating-pair [14], chirped mirrors [15] or the Brewster prism-pair [16] - the subject of this mini-review. Prism-pairs can provide tuned compensation with ultra-low loss of up to two orders of dispersion (GDD and sometimes an additional higher order), along with simple amplitude control using a slit or transmission mask in the dispersive arm. Due to the low loss of the prism-pair, it is often the main ‘tool of choice’ for intra-cavity applications [17-19], low light level spectroscopy [20-22], and quantum optics experiments [23-27]. This mini-review presents a simple and intuitive formulation of the total wavelength-dependent phase accumulated by light passing through a prism-pair, and demonstrates how this major component is used for tuned, precise control of dispersion and spectral phase.

A Single Prism
The analysis starts by reviewing the geometry of a single prism. When a ray passes through a prism at minimum deviation, the angles of refraction through the prism are symmetric [28], as illustrated in figure 1, resulting in:

\[
\theta_1 = \theta_d, \\
\theta_2 = \theta_d = \frac{\alpha}{2},
\]

where \(\alpha\) is the apex angle of the prism. If the entrance angle matches with the Brewster angle \(\theta_B\) (for a certain wavelength \(\lambda_0\)), the refraction angles obey.

Figure 1: Symmetry relations between the refraction angles in a prism. At minimum deviation, the entrance and exit angles are equal and the ray propagates through the prism parallel to its base.

The optical path of the deviated beam along a continuous ray, starting from point A, through multiple refractions in the 2nd prism until a wave front R1 is common for all wavelengths, shifting its position only results in a simple optical delay, hence, the position of R1 can be chosen freely to pass through the point A. The same argument applies also to R5, which can be chosen to pass through point C.

Consequently, for calculating the geometric dispersion, it is sufficient if the optical path through the entire prism-pair is reduced to the segment:

\[ P = AA' + CC' \]

Note that although this path is composed of free-space rays without refractions, it already takes into account refraction of the planar beam in the material. As illustrated in figure 4 (which shows the rays without the prisms for clarity), the optical path in Eq. 4 is identical to the segment EC, where the point C is the vertex of the 2nd prism. The conclusion is that the optical path of the deviated ray through the entire prism pair is simply given by:

\[ P = EC = ED + DC \]

where \( ED = R \cos \delta \theta \) and \( DC = H \cos \theta_n (\theta_n = \angle DCB) \).

Since EC is parallel to AA’ and R2 is parallel to R4, one can see that \( \theta_n \) is also the angle between R2 and the deviated ray (blue line) in the 1st prism, as illustrated in figure 5:

\[ \theta_n = \pi \cos \alpha - \theta_n - \delta \theta \]

Substituting Eq. 3 into Eq. 6 obtains:

\[ \theta_n = \pi - 2 \theta_n - \delta \theta = \alpha - \delta \theta \]

indicating that

\[ \Delta C = H \cos (\alpha - \delta \theta) = H \cos \alpha \cos \delta \theta + H \sin \alpha \sin \delta \theta - H \sin 2 \theta_n \sin \delta \theta \]

By substituting the above relations into Eq. 5, the total optical path through the prism-pair is:

\[ P = (R + H \cos \alpha) \cos \delta \theta + H \sin 2 \theta_n \sin \delta \theta \]

and the optical phase experienced by frequency \( \omega \) is

\[ \varphi = \omega P \]

Note that Eq. 8 was a generalization of the method presented in [31] in which only the special case of \( H = 0 \) is presented.

The expressions in equations [8] and [9] for the optical path \( P \)
and optical phase $\varphi$ are exact and can be easily used for numerical calculation of the spectral phase $\varphi(\omega)$ and its frequency derivatives $GDD = d^2\varphi / d\omega^2$, $G2 = d^3\varphi / d\omega^3$ and higher order dispersion terms. The refraction angle $\delta \theta$ for each wavelength/frequency can be calculated according to Snell’s law by using the prism’s apex angle and the Sellmeier formula for either $n(\lambda)$ or $n(\omega)$.

**Approximation of the Prism Angular Dispersion**

Although Eqs. 8 and 9 already allow complete calculation of the dispersion properties, much intuition can be gained by further developing the expressions with the assumption that the angle $\delta \theta(\lambda)$ is small. Replacing $\cos \vartheta_0 = 1 - \delta \theta^2 / 2$ and $\sin \vartheta_0 = \delta \theta$ yields:

$$P = (R + H \cos \alpha) \cdot (1 - \delta \theta^2 / 2) + (H \sin 2\theta_0) \cdot \delta \theta$$

[10]

The angle $\delta \theta$ can now be expressed using Snell’s law assuming small angles, such that: $\cos \vartheta_0 = 1$ and $\sin \vartheta_0 = \delta \theta$. It is assumed that the beam enters the 1st prism at the minimum deviation angle for a certain wavelength $\lambda$, that the entrance angle matches the Brewster angle $\theta_0$ for $\lambda$, and that the prism refractive index for $\lambda$ is $n(\lambda) = n_\beta$. The refraction index for the deviated beam $(\lambda \neq \lambda_0)$ is $n = n_\beta + \delta n(\lambda)$.

The angle of refraction inside the prism for the Brewster beam is $\beta$ (equal at both faces of the prism). As illustrated in figure 6, the angle of refraction for the deviated beam inside the prism is $\beta_0 + \delta \theta$. It is easy to show that the deviated beam will hit the exit face of the prism at an angle of $\beta = \beta_0 - \delta \vartheta$. The exit angle for the deviated beam will be $\theta_{exit} = \theta_0 + \delta \theta$. In addition, since at Brewster angle $\tan \beta_0 = n_\beta$ and $\vartheta_0 = \arcsin \left( \frac{\sin \vartheta_0}{\cos \vartheta_0} \right)$, the following relations hold: $\sin \vartheta_0 = \cos \beta_0$, $\cos \vartheta_0 = \sin \beta_0$.

Following Snell’s law from the entrance face to the exit, an approximation of the deviation angle $\delta \theta$ can be obtained. At the entrance:

$$\sin \theta_0 = n \sin \beta_0$$

[11]

Expanding the right hand side yields:

$$n \sin \beta_0 = (n_\beta + \delta n) \sin (\beta_0 + \delta \beta)$$

$$= (n_\beta + \delta n) \sin (\beta_0 \cos \delta \beta + \sin \beta_0 \sin \delta \beta)$$

$$\approx (n_\beta + \delta n) \sin (\beta_0 \cos \delta \beta + \sin \beta_0 \sin \delta \beta)$$

[12]

Substituting into Eq. 11 and dividing by $\vartheta_0$ (and noting that $\tan \theta_0 = n_\beta$) provides:

$$1 + \frac{\delta n}{n_\beta} + n_\beta \delta \beta = 1$$

[13]

Following similar logic at the exit face of the prism, obtains:

$$n \sin \beta_0 = \sin \theta_{exit}$$

[14]

Expanding both sides of Eq. 14 yields:

$$n \sin \beta_0 = (n_\beta + \delta n) \sin (\beta_0 - \delta \beta)$$

$$= n_\beta \sin \beta_0 + \delta n \sin \beta_0 \cos \delta \beta$$

$$\approx n_\beta \cos \theta_0 + \delta n \cos \theta_0 \sin \delta \theta - \delta n \sin \theta_0$$

[15]

$$\sin \theta_{exit} = \sin (\theta_0 + \delta \theta) = \sin \theta_0 \cos \delta \theta + \cos \theta_0 \sin \delta \theta$$

$$= \sin \theta_0 + \delta \vartheta \cos \theta_0$$

Equating both sides yields:

$$n_\beta \cos \theta_0 + \delta n \cos \theta_0 \sin \delta \theta - \delta n \sin \theta_0 = \sin \theta_0 + \delta \vartheta \cos \theta_0$$

[16]

Dividing Eq. 16 by $\sin \theta_0$ provides:

$$1 + \frac{\delta n}{n_\beta} - \delta n \approx 1 + \frac{\delta \vartheta}{n_\beta}$$

$$\delta \theta = 2 \delta \vartheta = 2 \left( n - n_\beta \right)$$

[17]

Substituting Eq. 13 into Eq. 17 yields:

$$\delta \theta = 2 \delta \vartheta = 2 \left( n - n_\beta \right)$$

[18]

Finally, Eq. 18 can be substituted into Eq. 8 and Eq. 9 to retrieve the total wavelength dependent phase through the prism-pair. Since the wavelength/frequency dependence is now only in $\delta \theta(\lambda)$, a simple expression for the $GDD = d^2 \varphi / d\omega^2$ can be derived:

$$\frac{d^2 \varphi}{d\omega^2} = \frac{2}{c} \left( B - 2A \delta \theta \right) \left( \frac{dn}{d\omega} + \omega \frac{dn}{d\omega} \right) - 4A \left( \frac{dn}{d\omega} \right)^2$$

[19]

where $\lambda = R + H \cos \alpha$ and $B = H \sin \theta_0$. The wavelength dependent refractive index of the prisms $n$ can be obtained from the Sellmeier formula.

The exact spectral phase and any of its derivatives $(d^n \varphi / d\omega^n)$ can be easily calculated using the chain rule [32]:

$$\frac{dn}{d\omega} = \frac{\lambda^2}{2 \pi c}$$

$$\frac{d^n}{d\omega^n} = \frac{\lambda^2}{2 \pi c} \left( \frac{dn}{d\omega} \right)^n$$

[20]

For typical optical bandwidths it is safe to assume that $B \gg 2A \delta \theta$ and that $R \gg H$, since $R \approx 10-50$ cm and $H \approx 10$ mm are common values. Thus, it is intuitive to think of $A$ as the distance between the prisms $(A = B)$, and of $B$ as the propagation distance inside the prisms. Further approximation can be made since for most practical optical materials $\frac{dn}{d\omega} \ll \omega \left( \frac{dn}{d\omega} \right)^2$. Hence, the total GDD of the prism pair is the sum of two parts: the accumulated GDD from the material dispersion due to propagation through the prisms and an additional negative GDD resulting from the geometric dispersion from the path between the prisms:

$$\frac{d^2 \varphi}{d\omega^2} = \frac{2B \delta \theta + 4A \delta \theta^2}{c^{n+1}} \left( \frac{dn}{d\omega} \right)^2$$

[21]

The geometric dispersion in the second part attributes always a negative GDD for any material (independent of the sign of $dn / d\omega$), whereas the first part depends on the material dispersion, which may be either positive (as is usually the case in the visible or NIR range), or negative (as is usually the case for the IR in most materials). Hence, a simple prism-pair offers tunable GDD, both negative and positive, for visible and NIR wavelengths, but for the IR range it will commonly provide only negative GDD. Tuned positive dispersion in the IR range can still be obtained by inserting a 1x1 telescope between the prisms that can flip the sign of the geometric dispersion by imaging the first prism beyond the 2nd prism, effectively generating a “negative distance” $R$ between the prisms [23].

**Summary**

The performance of the Brewster prism-pair was reviewed - a common major component of ultrafast spectroscopy apparatus. The total spectral phase was calculated as accumulated by broadband light.
in passage through the prism-pair. Following a simple and intuitive approach using the concept of wavefronts, it was showed how the total optical path through a prism pair can be reduced to the path of a non-continuous beam, hence avoiding unnecessary computations of multiple refractions inside the prisms. Finally, the total phase and any of its derivatives can be easily calculated. Specifically, by careful choice of the two degrees of freedom of the prism pair R and H, it is possible to compensate two orders of dispersion simultaneously (e.g. $d^2 \phi / d\omega^2$ and $d^3 \phi / d\omega^3$), which is crucial when using ultra-broadband light to maintain high temporal resolution [23].
